## SECULAR ACCELERATIONS IN THE LONGITUDES OF THE SATELLITES OF MARS

By BEVAN P. SHARPLESS
(Communicated by the Superintendent, U. S. Naval Observatory)

Numerical values for the orbital elements of the satellites of Mars were derived by H. Struve, ${ }^{1,2}$ Burton ${ }^{3}$ and others. On page 160 of Burton's paper are found tables of the observed longitudes of the satellites with reduction to the common epoch 1900.0. The tables also contain the probable errors of the observed longitudes. It is intended to use these data and, in addition, unpublished material resulting from solutions of observations made at Washington in 1939 and 194I, to investigate the possibility of accelerations of the longitudes of the satellites.

Burton assumed the following values for longitude at epoch and mean daily motion, which for convenience will be used here:

|  | Lóng. at r900.0 | Mean Daily Motion |
| :--- | :---: | :---: |
| Deimos | $286^{\circ} .70$ | $285^{\circ} .16190$ |
| Phobos | 19.67 | II28.844I3 |

Since there is a large variation in the probable errors of individually observed longitudes and since the observations occur in groups, it will be convenient to take group means by weighting in accordance with the probable errors. We then have five group means (taking off the longitudes at 1900 given above) :

| Date | Days from $\begin{gathered}\text { Deimos } \\ 1900.0\end{gathered}$ | $\Delta l$ | p.e. |
| :---: | :---: | :---: | :---: |
| 1879. 16 | - 7610.2 | -0. 45 | $\pm{ }^{\circ} \mathrm{O} 7$ |
| 1894.79 | - 1901.5 | -0.03 | $\pm .04$ |
| 1909.72 | + 3551.2 | +0.36 | $\pm .02$ |
| 1926.17 | $+9559.0$ | +0.10 | $\pm .03$ |
| 1941. 66 | +15217.7 | +0.40 | $\pm .04$ |
| Date | Days from $\begin{gathered}\text { Phobos } \\ \text { I900.0 }\end{gathered}$ | $\Delta l$ | p.e. |
| 1879.23 | $-7587.8$ | +o. 60 | $\pm{ }^{\circ} 2 \mathrm{I}$ |
| 1894.46 | - 2022.9 | -0.26 | $\pm .08$ |
| 1909.69 | $+3540.6$ | -0.49 | $\pm .09$ |
| 1925.26 | + 9225.5 | +0.41 | $\pm .10$ |
| 1941.66 | +15214.8 | +2.24 | $\pm .13$ |

Solving conditional equations of the form

$$
a+b\left(t_{d}-1900.0\right)+c\left(t_{y}-1900.0\right)^{2}=\Delta l
$$

where $t_{d}, t_{y}=$ time measured in days and years respectively, and giving equal weight to each equation, we find

|  | Deimos |  | Phobos |  |
| :---: | :---: | :---: | :---: | :---: |
| $a \quad+0$ | $+0^{\circ} .057 \pm .097$ |  | -0. ${ }^{\circ} 467 \pm{ }^{\circ} .100$ |  |
| $b+o$ | 00047 | 000013 | -0.000037 | 000013 |
| $c$ | $000266=$ | 000164 | +o.001882 | 000171 |
| Solution | [vv] | p.e. I | [vv] | p.e. I |
| Linear | 0.1443 | $\pm{ }^{\circ} 148$ | 2.9776 | $\pm{ }^{\circ} 672$ |
| Parabolic | 0.0854 | $\pm$. 139 | 0.0120 | $\pm .050$ |

In the case of Deimos it is seen that little improvement is obtained from the parabolic solution. If an acceleration exists, more observations

will be required to confirm it. The results for Phobos show a marked improvement when the parabolic term is included. The coefficient of the square of the time comes out about eleven times its probable error. An improvement in the place of the satellite will result if we include this term; in fact it is necessary if we wish to predict the position of the satellite accurately in the latter half of the twentieth century.
It is not intended that this should be considered a definitive solution for the motion in longitude. The expression for the longitude contains a periodic term which is subject to revision. The effect of the fluctuation in astronomical time
was examined, and it was found that it was nearly linear over the period of time under consideration. A trial solution showed only negligible effects on the accelerations.

# OBSERVATIONS OF FV CARINAE 1875: - $10 \mathrm{~h} 38 \mathrm{~m},-61^{\circ} 18^{\prime}$ 

By HAROLD L. ALDEN

The following observations of the eclipsing variable FV Carinae are in continuation of those previously published in this journal. ${ }^{1}$ They have been made and treated in the same manner as before, the mean epochs of minimum having been formed in the way described in that paper.

Table I contains the heliocentric time of the mid-exposure, the estimated magnitude, and the exposure time in minutes. Table II gives the weighted mean epochs of minimum for each year, the observations on each night being reduced to the same epoch with an approximate period. The residuals given under I and II are from the corresponding formulae and form a continuation of Table III of the earlier paper.

The former residuals indicate that a longer

| 1943 | 2430877.1094 | +1407 | 2.0 | +.0125 | - | . 0262 |

period is necessary to satisfy the Yale observations if a linear formula is used. However a suitable period would throw some of Hertzsprung's ${ }^{2}$ observations made in 1924-6 on portions of the light curve where it is doubtful if he could have observed the star as fainter than normal. The residuals under II show that the coefficient of the secular term is too large. A value about half as great would satisfy the later observations
